

of the organism and its passage through soil has, therefore, an important bearing on the technique of seed inoculation.

A modification of Winogradsky's technique for staining bacteria in soil (1924, *Comptes rend. Acad. Sci.*, vol. clxxxix, p. 367) has enabled the present authors to follow the passage of the nodule organism through sterile soil. It has been found that they will progress through light soil at an approximate rate of one inch in 24 hours, though the rate is affected by the soil texture. When a drop of water containing the bacteria in the rod stage is added to sterile soil, the spread of the organisms from the point of inoculation does not begin until after a considerable interval, and its commencement is accompanied by the conversion of a large percentage of the bacteria into cocci. If the inoculum consists of a suspension in milk, the bacteria begin to spread through the soil after a shorter interval. This is perhaps an explanation of the successful results obtained by using a suspension of the bacteria in skim milk for wetting the seed, a technique now practised in Scandinavia for inoculating lucerne. The effect of milk also emphasises how important is the nature of the liquid used in making the bacterial suspension for seed inoculation.

Bewley and Hutchinson (*Journ. Agric. Sci.*, 1921, vol. x, p. 144) found that the production of the motile coccoid stage of *Bacillus radicum* was greatly stimulated by the presence of phosphates. The effect of inoculating sterile soil with a suspension of the bacteria in skim milk containing 0.1 per cent. soluble calcium phosphate, $\text{CaH}_4(\text{PO}_4)_2 + 2\text{H}_2\text{O}$, was therefore tested. It was then found that the spread of the organisms from the point of inoculation commenced almost immediately. It seemed probable that the use of a bacterial suspension in the above solution for wetting the seed would increase the chances of nodule formation by hastening the spread of organisms from the seed-coat, and thus increasing the volume of soil explored by them in a given time. Pot culture tests of seed inoculation were therefore made with lucerne, in which a bacterial suspension in a 0.1 per cent. solution of $\text{CaH}_4(\text{PO}_4)_2 + 2\text{H}_2\text{O}$ in skim milk was compared with a suspension in skim milk alone, such as is now in practical use. On averages of 10 parallel pots, increases in nodule numbers of 93 per cent. and 73 per cent. were obtained in two experiments by the addition of phosphate to the milk. There was also a favourable effect on the yield of the crop. The work is being continued and will be published in detail at a later date.

Capillary Action: Transpiration.

IF a capillary tube, A, Fig. 1, with a wedge-shaped cut in it at a distance of about 10 mm. from its upper end, at right angles to, and deep enough to make a breach in one side of its aperture, is lowered slowly into water the rising column of water pauses for an instant when it reaches the gap, which is necessarily higher than the surface of the water into which the tube is being dipped, and then leaps past it and rises to the top of the aperture.

When this tube is fixed in a cork as shown in Fig. 1; the cork inserted as a stopper into the mouth of a cylindrical vessel, B, containing water; the vessel, B, fixed in a circular piece of cork which acts as a stand for it; and a small sheet of thin blotting paper, *b*, drawn far enough into the cut to touch the thread of water in the aperture, the capillary tube acts the part

of the stem of a plant, the blotting paper that of a leaf, and transpiration commences and continues uninterrupted through the latter so long as the water lasts. A current of water flows up the aperture of the capillary tube and through the gap in it to the blotting paper from which it is evaporated continuously without creating any visible disturbance in the thread of water contained in that part of the aperture above the gap. As the surface of the water inside the vessel, B, is being lowered, air flows into the space above it through a fine capillary tube, *a*, which passes through the cork near the larger tube.

In an experiment with this apparatus carried out in May 1922, the dimensions of the sheet of blotting paper were 33 mm. by 43 mm. The edge of the sheet was drawn into the cut by means of a thread which passed round the back of the capillary tube and slightly compressed a small india-rubber tube which acted as a spring to keep it taut as shown. On placing the apparatus on one scale of a chemical balance in a glass case, in which there

FIG. 1.—Capillary tube to illustrate transpiration. Half real size.

was also a basin containing chloride of calcium, and balancing it with weights in the other scale, it was found that when both scales were left free to move, one rose and the other fell so rapidly and continuously that their movement was clearly visible to the unaided eye.

Observed during a period of 491 minutes, it was found that the total weight of water evaporated in that time amounted to 1.1958 gm., or at the rate of 2.43 mgm. per minute. The aperture of the capillary tube was elliptical. Its area in cross-section, ascertained by calibration with a thread of mercury 93.2 mm. in length at 20° C. and weighing 3.21 mgm., was 0.02542 mm². It was thus equal to that of a circle 0.18 mm. in diameter, and the velocity of flow of water in the aperture was at the rate of 95.5 mm. per minute.

The Ballistic Theory of Light and the Michelson-Morley Experiment.

IN a note regarding my theory of variable stars, published in NATURE of October 11, p. 550, it is suggested that some difficulties would probably arise on the ground of the Michelson-Morley experiment. As the point is a very important one, I should be glad if space can be given me to make it clear.

The ballistic principle, on which my theory is entirely based, requires that light emitted from a source movable relatively to the observer shall exhibit a velocity compounded of the common velocity *c* and of that of the source. As in the Michelson-Morley experiment the source is at rest in respect to the observer, the ballistic principle requires that light travels with the same velocity *c* in all directions. Hence no displacement of the interference fringes may appear in revolving the whole apparatus. The negative result of Michelson-Morley experiment evidently agrees with the ballistic theory. The same

agreement must hold, in all the experiments directed to detect the total motion, for the ballistic principle has been just introduced from Ritz for the purpose of extending the mechanical principle of relativity to all physical phenomena. This means that the ballistic theory is a *relativistic* one, like that of Einstein, with the two advantages of preserving classical mechanics and of explaining variable stars.

For the sake of completeness, it must be remembered that only in one event would the Michelson-Morley experiment trouble the ballistic theory, that is, only if in repeating the experiment with extra-terrestrial light the result were also negative. Of course, an astronomical light source is not dragged by the earth; light speed, therefore, on the ballistic theory should appear to a terrestrial observer different towards and normal to the motion. Thus, an effect should be expected. As a matter of fact, this experiment proposed by myself in 1912 (*Nuovo Cim.* vol. 3, p. 345, 1912; *Phys. Zeit.* vol. 13, p. 1129, 1912), and recently attempted (R. Tomaschek, *Ann. d. Phys.* 73, p. 105, 1924), cannot give a decisive result, for many difficulties increase when the light falls on a movable mirror, as I have already pointed out (*Ann. d. Phys.*, 75, p. 195, 1924).

In conclusion, ballistic theories are very promising, because they enable us to explain all the phenomena of classical optics and electromagnetism, including the deflexion of light rays near the sun, and they are also fruitful in explaining variable stars, while they finally reconcile both the undulatory and the quantum theories required by recent discoveries.

The Rare Gases of the Atmosphere.

ONE of the unsolved questions of geophysics is whether the earth's atmosphere is mainly primitive, or whether its constituents have for the most part been evolved from the interior of the earth since solidification. Dr. Aston's letter (*NATURE*, Nov. 29, p. 786) may help to answer this question. The tendency of a gravitating planet to collect heavier molecules to itself, and in certain circumstances to lose the lighter ones, would not by itself account for the rarity of the inert gases. Xenon and krypton have the highest molecular weights of all the atmospheric gases, and would therefore be the most abundant if this were the sole explanation. Possibly the ability of other elements to form stable solid and liquid compounds has co-operated. If so, we may contemplate a heated primitive earth surrounded by a tenuous atmosphere consisting largely of the rare gases as at present represented, with the possible exception of helium. The greater part of the atmosphere, the water, and perhaps the helium, would have been emitted from the interior in the course of the earth's development.

I am much indebted to the reviewer for his careful and kind notice, in *NATURE* of November 22, of my book "The Earth." He has, however, misunderstood me in regarding as a lower limit my estimate of 0.14 astronomical unit as the radius of the primitive sun, at the time of the tidal encounter. It is an upper limit, based on the fact that the sun would have been too cold to be gaseous if its size were any greater. I doubt whether any serious change will be necessitated by the sudden death of the giant and dwarf theory while my book was in the press, but cannot as yet be sure.

The Temperature of Mars.

IN a recent paper (Pub. Ast. Soc. of the Pacific), Nicholson and Pettit calculate the temperature of the planet Mars, based on their radiation measures made at Mount Wilson. Their confidence is placed on measures made in the region 8 to 14 μ , by the use of filter screens, and an emissivity of unity is assumed for all wave-lengths. However, Mars, being probably composed of material not unlike the earth, would radiate more like sand or quartz than like a black body, and it can be calculated from curves given by Wood ("Physical Optics") and data given by Rosenthal (*Wied. Ann.* 68, p. 783), that the average ratio of the emissivity of quartz to that of a black body in the region 8 to 14 μ , is 0.819. The values of the emissivity of quartz given are far below that of a black body between 8 and 10 μ ; they are nearly the same from 10 to 14 μ ; the average ratio is taken.

It is believed that temperature calculations using this value for the emissivity, and the fourth power radiation law, will be more correct than when an emissivity of unity is assumed. For a given amount of received radiation, the temperature of the radiating body will be higher for a lower emissivity. Accordingly, the temperatures T given by Nicholson and Pettit have been recalculated by applying the method separately to each value of T.

$$\frac{T^4}{T_c^4} = 0.819.$$

Low-Voltage Arc Spectra of Copper.

IN my letter which appeared in *NATURE* of October 4, p. 501, I reported work I had carried out on the low-voltage arc in copper vapour. I have since then succeeded in obtaining the line absorption of normal copper vapour. The lines which are certainly absorbed, and which, therefore, should be 15 combinations, are:

3247.55 2244.24
3273.97 2225.67
2492.14 2165.06
2441.63

With slight uncertainty there are also the lines:
2181.68
2024.33

In addition, I find from combinations that 2178.91 should also be absorbed, but this is not sufficiently resolved from 2179.39 by the small spectrograph used.

By subtraction from the term 15, the above lines give energy-levels which are all confirmed by combinations with other known terms of the copper arc spectrum. From the arc lines previously reported I have also calculated a number of other terms.

A paper is being written incorporating all these results.
